*J Med Genet* 2007;44:353–362. doi: 10.1136/jmg.2007.048991

Lynch syndrome (hereditary non-polyposis colorectal cancer) is characterised by the development of colorectal cancer, endometrial cancer and various other cancers, and is caused by a mutation in one of the mismatch repair genes: *MLH1*, *MSH2*, *MSH6* or *PMS2*. The discovery of these genes, 15 years ago, has led to the identification of large numbers of affected families. In April 2006, a workshop was organised by a group of European experts in hereditary gastrointestinal cancer (the Mallorca-group), aiming to establish guidelines for the clinical management of Lynch syndrome. 21 experts from nine European countries participated in this workshop. Prior to the meeting, various participants prepared the key management issues of debate according to the latest publications. A systematic literature search using Pubmed and the Cochrane Database of Systematic Reviews reference lists of retrieved articles and manual searches of relevant articles was performed. During the workshop, all recommendations were discussed in detail. Because most of the studies that form the basis for the recommendations were descriptive and/or retrospective in nature, many of them were based on expert opinion. The guidelines described in this manuscript may be helpful for the appropriate management of families with Lynch syndrome. Prospective controlled studies should be undertaken to improve further the care of these families.

truncating mutations in the (*APC*) adenomatosis polyposis coli gene. Recently, the *MUTYH* (mutY homologue (*Escherichia coli*)) gene has been identified as a further polyposis gene. The associated disorder has been termed *MUTYH*-associated polyposis or MAP, and displays an autosomal recessive pattern of inheritance.<sup>2</sup>

In April 2006, a workshop was organised by a group of European experts on hereditary gastrointestinal cancer in Palma de Mallorca. The main purpose of this meeting was to establish guidelines for the clinical management of the most common inherited forms of CRC and to identify collaborative studies. Twenty-one experts from nine European countries participated in this workshop. Prior to the meeting, various participants were requested to prepare the key management issues of debate according to the latest publications. During the workshop, all recommendations were discussed in detail. In this review, we report the outcome of the discussion with respect to Lynch syndrome.

A systematic literature search using Pubmed and the Cochrane Database of Systematic Reviews, reference lists of retrieved articles and manual searches of relevant articles was performed. Search terms included HNPCC, Lynch syndrome, microsatellite instability and MMR genes. Only peer-reviewed English articles were included. Table 1 shows the criteria that were used for evaluation of studies on management, for categorisation of evidence that they presented and for the strength of the recommendations that we made.

## CHARACTERISTICS OF LYNCH SYNDROME

Carriers of an MMR gene mutation have a high risk of developing CRC, endometrial cancer and other associated cancers. Table 2 summarises the various types of cancers and the reported risks.<sup>3–10</sup> The cancers observed in families with Lynch syndrome are diagnosed at an unusually early age, and may be multiple. The MMR defect leads to instability in microsatellites of tumour DNA; this is called microsatellite instability (MSI). This feature can be found in >90% of colon cancers associated with Lynch syndrome, whereas in sporadic CRC it is found in about 15% of cases.

**Abbreviations:** CPT11, irinotecan; CRC, colorectal cancer; FAP, familial adenomatous polyposis; FU, fluorouracil; HNPCC, hereditary non-polyposis colorectal cancer; IHC, immunohistochemical; MSI, microsatellite instability; MMR, mismatch repair; QoL, quality of life; TVU, transvaginal ultrasound

Environmental factors play a dominant role in the aetiology of most colorectal cancers (CRCs). However, inherited genetic factors are also significant in between 15% and 30% of cases. In about 5% of all cases, CRC is associated with a highly penetrant dominant or recessive inherited syndrome. The most common of these is Lynch syndrome (hereditary non-polyposis colorectal cancer (HNPCC)).<sup>1</sup> It is characterised by the development of CRC, endometrial cancer and various other cancers, and is caused by a mutation in one of the mismatch repair (MMR) genes: *MLH1*, *MSH2*, *MSH6* or *PMS2*. Familial adenomatous polyposis (FAP) is another well-described inherited syndrome, and is responsible for <1% of all CRC cases. It is characterised by the development of hundreds to thousands of adenomas in the colorectum. Almost all patients develop CRC if they are not identified and treated at an early stage. FAP is transmitted as an autosomal dominant trait, and is caused by

With immunohistochemical (IHC) analysis using antibodies against the four MMR proteins, loss of protein expression of the causative gene can be shown.

In 1989, the Amsterdam criteria were proposed in order to provide uniform family material required for international collaborative studies.<sup>11</sup> In 1999, these criteria were revised and now include various extra-colonic tumours.<sup>12</sup> In 1997, the Bethesda guidelines were developed to identify individuals with CRC who should be tested for MSI.<sup>13, 14</sup> These guidelines were revised in 2004.<sup>15</sup> Box 1 shows the revised Amsterdam criteria and Bethesda guidelines. After the discovery of mutations in the MMR genes, 14 years ago, the syndrome finally received the attention in the medical community that it deserved. This has led to the identification of large numbers of affected families.

## TERMINOLOGY

Various names for Lynch syndrome have been used in the past century. A workshop in Amsterdam in 1989 agreed upon the name "HNPCC", because at that time the syndrome was unknown to most doctors. This name clarified that the syndrome described an inherited form of CRC. The appropriateness of the name was discussed again at an international meeting in Bethesda in 2004. Most participants considered the term HNPCC to be inappropriate, since the syndrome is also associated with many other tumours. It was proposed that the name "Lynch syndrome" should be reintroduced, and that this name should be reserved for families with strong evidence of MMR deficiency—for example, by the presence of an MMR defect or by the presence of MSI in tumours.<sup>15</sup> The European group agreed that this name is the best available name for the syndrome. The group suggests that families that meet the original Amsterdam criteria but do not have evidence for MMR deficiency are referred to as having familial CRC.

## IDENTIFICATION

Identification of family members carrying an MMR gene defect is important, as colonoscopic surveillance may be restricted to these individuals, whereas those without a gene defect may be reassured and spared intensified surveillance. Mutation analysis is rather expensive, as four genes may have to be analysed.

**Table 2** Lifetime risk of cancer reported in families with an identified mismatch repair mutation

Colorectal cancer (men)	28–75%
Colorectal cancer (women)	24–52%
Endometrial cancer	27–71%
Ovarian cancer	3–13%
Gastric cancer	2–13%
Urinary tract cancer	1–12%
Brain tumour	1–4%
Bile duct/gallbladder cancer	2%
Small-bowel cancer	4–7%

Moreover, comprehensive screening of these genes is required, as their mutational spectra are wide.

Currently, the Amsterdam II/Revised Bethesda criteria are used to select patients with CRC for molecular genetic and/or IHC analysis of the tumour, and those with evidence of MSI or loss of MMR expression are offered mutation analysis.

Question: are the Amsterdam II criteria and the revised Bethesda guidelines appropriate to select families for molecular genetic analysis of tumours?

One way to establish whether these criteria are appropriate is to determine the proportion of cases with inherited MMR gene mutations that they would miss in a series of unselected patients with CRC. We found six studies in which either MSI or IHC analysis or both tests were performed as the primary screening tool in prospective and unselected series of patients with CRC (table 3).<sup>16–21</sup>

Previous studies have shown that the yield of mutation analysis (positive predictive value) in families that meet the Amsterdam criteria is approximately 50%, and that the yield in families that meet the Bethesda criteria is between 10% and 20%.<sup>22</sup> The six studies showed that the sensitivity of the Amsterdam criteria for the detection of mutations was 40% and that the sensitivity of the Bethesda guidelines was about 90% (table 3). This means that if the revised Bethesda guidelines had been used, about 10% of the mutation carriers would have been missed, mostly patients with CRC diagnosed between age 50 and 60 years. According to the revised Bethesda guidelines, in patients with CRC diagnosed in their 50s, special attention should be given to the presence of pathological features that suggest Lynch syndrome (eg, the presence of tumour-infiltrating lymphocytes). If these features are found, the tumours should be tested for MSI. Unfortunately, the studies summarised in table 3 did not present data on the pathological examination of the cancers in these cases.

In view of the high costs of testing all CRCs for MSI or loss of MMR protein, the group believed that the revised Bethesda guidelines are an appropriate tool to help in selecting patients for genetic testing. An alternative approach is to use computer models that are currently being evaluated.<sup>23, 24</sup>

Because of the accumulating evidence that MSI is a predictive factor for response to 5-fluorouracil (FU)-based chemotherapy, the group expects that these tests will be performed in an increasing number (if not all) of patients with CRC in the near future.

Conclusion: the revised Bethesda guidelines are appropriate tools to help in selecting families for molecular genetic and/or IHC analysis of tumours (category of evidence II)

Question: which test, MSI or IHC, has the best sensitivity for the detection of MMR gene mutations?

In the literature, many studies have been published on the results of MSI or IHC analysis for the identification of MMR-gene mutations. However, most studies were retrospective and the methods that were used varied widely. The number of markers for MSI analysis ranged from 1 to >10. For IHC analysis, most studies used two antibodies (MLH1, MSH2)

**Box 1 Amsterdam criteria II and revised Bethesda guidelines**

**Amsterdam criteria II**

There should be at least three relatives with colorectal cancer (CRC) or with a Lynch syndrome-associated cancer: cancer of the endometrium, small bowel, ureter or renal pelvis.

- one relative should be a first-degree relative of the other two,
- at least two successive generations should be affected,
- at least one tumour should be diagnosed before the age of 50 years,
- FAP should be excluded in the CRC case if any,
- tumours should be verified by histopathological examination.

**Revised Bethesda guidelines**

1. CRC diagnosed in a patient aged <50 years.
2. Presence of synchronous, metachronous colorectal or other Lynch syndrome-related tumours,\* regardless of age.
3. CRC with MSI-H phenotype diagnosed in a patient aged <60 years.
4. Patient with CRC and a first-degree relative with a Lynch syndrome-related tumour, with one of the cancers diagnosed at age <50 years.
5. Patient with CRC with two or more first-degree or second-degree relatives with a Lynch syndrome-related tumour, regardless of age.

\*Lynch syndrome-related tumours include colorectal, endometrial, stomach, ovarian, pancreas, ureter, renal pelvis, biliary tract and brain tumours, sebaceous gland adenomas and keratoacanthomas, and carcinoma of the small bowel.

against the MMR proteins; other studies used three or four antibodies (MLH1, MSH2, MSH6, PMS2). In the studies in which both MSI analysis and IHC analysis have been used prospectively (table 4), the sensitivity of MSI analysis was slightly better than that of IHC analysis.<sup>17 19–21 24–28</sup> The false negatives with IHC might be due to the fact that the antibody detects a fragment of the truncated protein. There is one large (German) study that evaluated the outcome of these tests prospectively in families that meet the Amsterdam, Bethesda or slightly modified criteria. In this study, MSI analysis (using the

Bethesda set of five markers) and IHC analysis (two antibodies) were performed in 1119 index patients.<sup>26</sup> Altogether, 230 pathogenic MMR gene mutations were identified. The sensitivity of MSI analysis was 100% and that of IHC analysis was 94%. A Dutch study showed that by adding antibodies against PMS2 the sensitivity for the detection of MLH1 mutations increased.<sup>29</sup> Had the German investigators used all four antibodies, the sensitivity of IHC might have been higher.

The advantage of IHC is that it may direct mutation analysis because the pattern of staining is suggestive of the underlying gene defect. This is the reason for most authors recommending the use of IHC as the first step in families with a high probability of carrying a mutation (eg, families that meet the Amsterdam criteria or families with a high predicted probability based on calculations using computer models (fig 1)).<sup>22–24 26</sup> Because of the incomplete sensitivity of IHC analysis, MSI is recommended for cases with a high prior probability of Lynch syndrome but with apparently normal expression of the MMR proteins. In families with a moderately increased probability of carrying a mutation, depending on the experience of the centre, either MSI or IHC analysis might be used as the first step to exclude the presence of MMR deficiency. Preferably, colon tumour tissue is used for MSI/IHC analysis. However, if colon tumour tissue is not available, other tumours—for example, endometrial cancer or adenomatous polyp—may be analysed. Unfortunately, the few studies that are available showed that the sensitivity of MSI/IHC for MMR mutations in these tumour tissues was lower than that of the same analysis of colon cancers.<sup>31 32</sup>

Because interpretation of the pedigree information, the pathology of the tumour and the outcome of MSI and IHC testing can be complex, our group advises that these data be discussed together by a multidisciplinary team.

Conclusion: the sensitivity of MSI analysis is slightly higher than that of IHC analysis (category of evidence II). In families with a high probability of having a mutation (Amsterdam II criteria, computer models), IHC is the best first step because it may direct mutation analysis. In other families, either MSI or IHC analysis might be used as the first step. The results of pedigree analysis and MSI/IHC analysis should be discussed in a multidisciplinary setting (pathologist, clinical/molecular geneticist, gastroenterologist, surgeon, etc; grade C).

**SURVEILLANCE OF THE COLORECTUM**

Studies have shown that the adenoma–carcinoma sequence may also be applied in the development of CRC in families with Lynch syndrome. Since the 1980s, colonoscopic surveillance has

been recommended for these families. The following question is relevant.

Question: does colonoscopic surveillance of the colorectum lead to early detection of CRC or adenoma and reduction of CRC-related mortality?

A literature search showed that nine studies have addressed at least the first part of the question.<sup>33-41</sup> Table 5 summarises the nature of these studies, the number of families involved and the categories of evidence produced. All the studies showed that surveillance led to the detection of CRC at an earlier stage compared with the stage in historical controls. The only prospective controlled trial showed that surveillance led to a 63% reduction of CRC.<sup>38</sup> Two studies assessed the effect of surveillance on CRC-associated mortality. A Finnish study showed that colonoscopic surveillance significantly decreased the mortality associated with CRC.<sup>38, 42</sup> A study from the Netherlands evaluated the relative mortality in a large series of families over a period of 45 years. In the Netherlands, a national registry of families with Lynch syndrome was established in 1985 to promote the identification of such families and to encourage participation in surveillance programmes.<sup>35</sup> Mortality in these families has decreased significantly in the last 15 years.

Conclusion: periodic examination by colonoscopy leads to the detection of CRC at an earlier stage, to a 63% reduction of the risk of CRC and to a significant reduction of the mortality associated with CRC (category of evidence IIb).

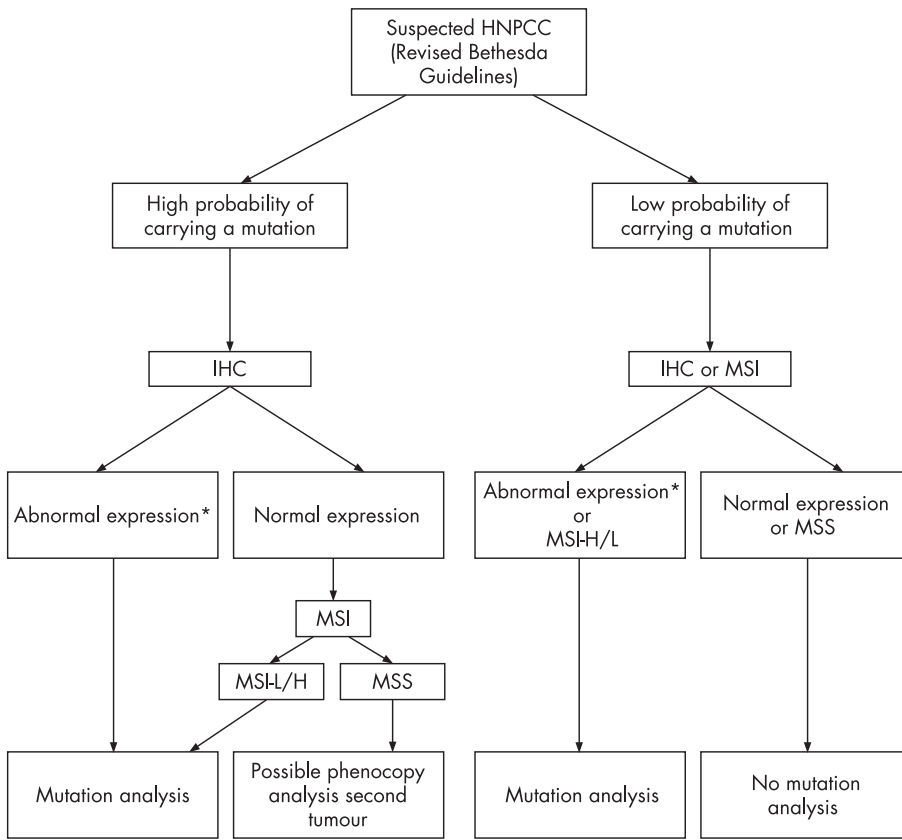

The protocols that have been used in studies of surveillance have varied with respect to the surveillance intervals. Some studies advised a 3-yearly colonoscopy and others colonoscopy every year.

Question: what is the optimal surveillance protocol for Lynch syndrome in terms of surveillance interval?

A search of the literature did not reveal any studies that compared different surveillance intervals. The Finnish trial showed that 3-yearly colonoscopy significantly reduced the incidence of CRC and CRC-related mortality.<sup>38</sup> Therefore, the only evidence available suggests that a 3-yearly interval may be adequate. However, several observational studies suggest that (interval) cancers can occur within a 3-year interval after colonoscopy. In a Finnish study on surveillance of 56 families, the stage distribution of CRC was significantly more favourable in patients (n = 35) with cancer detected by surveillance than in patients (n = 115) with symptomatic presentation of CRC.<sup>39</sup> However, a total of 21 cancers were diagnosed after a previous “clean” colonoscopy, and half of them were diagnosed within (or at) an interval of 3 years. These included two Dukes C cancers diagnosed 15 and 20 months after the previous examination. In a Dutch long-term follow-up study, a number of interval cancers were also observed. Advanced cancers (Dukes C) were only observed at intervals of >2 years, whereas all Dukes A and B tumours were detected within an interval of <2 years. These observations, together with the finding that adenomas observed in HNPCC more often show high-grade dysplasia and villosity, suggest that the adenoma–carcinoma sequence is accelerated in Lynch syndrome.<sup>32, 43</sup> Therefore, the most appropriate surveillance interval probably lies between 1 and 2 years. In highly selected cases—for example, mutation carriers who have recurrent adenomas—a prophylactic subtotal colectomy may be discussed as an option.

Conclusion: a 3-year interval is proven to be (at least partly) effective (category of evidence IIb); in view of the observation of advanced CRC detected 2–3 years after colonoscopy, the optimal interval probably lies between 1 and 2 years (category of evidence III, grade C).

Question: at what age should surveillance be started and at which age might surveillance be discontinued?

**Figure 1** Strategy for identification of patients with colorectal cancer with a mismatch repair gene defect. \*If MLH1 expression is lost, DNA analysis of BRAF in the tumour can be performed because the presence of a BRAF-V600E mutation makes hereditary non-polyposis colorectal cancer (HNPCC) very unlikely. IHC, immunohistochemical; MSI, microsatellite instability; MSS, microsatellite stability.<sup>30</sup>

Many studies have shown that the risk of developing CRC before the age of 25 years is very low.<sup>7-10</sup> In a series of 246 CRC from families with Lynch syndrome known at the Dutch HNPCC Registry, only 2 (0.8%) patients developed CRC before the age of 20 years and another two between age 20 and 25 years.<sup>44</sup> Based on these data, the group advises to start surveillance between age 20 and 25 years. In the literature, recommendations regarding the upper age limit of surveillance are very sparse. One study has reported that the risk of mutation carriers aged 70–75 years developing CRC in the next 10 years is significant.<sup>44</sup> However, at the age of 80 years, they found that the risk of developing CRC in the next 10 years relative to their life expectancy was low. Based on these findings, the authors recommended continuing surveillance up to the age of 80 years in mutation carriers if they were in good health. However, the European group advises that decisions on

the upper age limit of surveillance should be made on an individual basis. For example, in a 75-year-old mutation carrier with severe cardiovascular disease, surveillance can be discontinued. On the other hand, in an 80-year-old mutation carrier who is still in good health, especially if there is a personal history of adenomas and colon cancer, it is reasonable to continue surveillance.

**Conclusion:** surveillance should start between age 20 and 25 years. Decisions on the upper age limit of surveillance depend on the patient’s general state of health and should be made on an individual basis (category of evidence III, grade C).

**Question:** which surveillance protocol should be recommended in families with clustering of CRC without evidence of MSI in the tumours?

In a significant proportion (approximately 30%) of families that meet the Amsterdam criteria, the results of the MSI and IHC analysis of the colorectal tumour(s) are negative.<sup>45</sup> Clustering of CRC by chance or genetic defects other than those of MMR may be responsible for the disease in such families, and they do not have Lynch syndrome. These families are characterised by a more advanced age of onset of CRC than in families with Lynch syndrome, and the absence of endometrial cancer and multiple tumours. A recent study reported that the risk of developing CRC in such families is increased only by a factor of 2.3.<sup>45</sup> Another study compared the results of surveillance in families with clustering of CRC with and without MSI.<sup>46</sup> The results showed that the yield of adenomas was the same in both types of families. However, CRC was identified only in the families with MSI tumours. In families without evidence for MMR deficiency, a less intensive colonoscopic surveillance programme (eg, colonoscopy: 1 ×/3–5 years, starting 5–10 years before the first diagnosis of CRC or at >45 years) might be appropriate. In view of the absence of

endometrial cancer in such families, surveillance of the endometrium is not indicated.

Conclusion: in families with clustering of CRC but without evidence of MMR deficiency (families without Lynch syndrome), a less intensive surveillance protocol is recommended—that is, colonoscopy at 3–5 year intervals, starting 5–10 years before the first diagnosis of CRC or at >45 years (category of evidence III, grade C)

### SURVEILLANCE OF THE ENDOMETRIUM/OVARY

Previous studies have shown that carriers of an MMR mutation have a high risk of developing endometrial cancer.<sup>7</sup> Although it is known that the majority of (sporadic) endometrial cancers are detected at an early stage, about 10–15% of patients with such tumours will ultimately die from metastatic disease. In view of this significant mortality and the high risk of developing endometrial cancer in families with Lynch syndrome, most authors advise surveillance of the endometrium.

Question: how effective is surveillance for endometrial cancer in families with Lynch syndrome?

British and Dutch investigators evaluated the outcome of surveillance of 269 women from families suspected of having Lynch syndrome.<sup>47–48</sup> The surveillance programme consisted of ultrasound every 1–2 years. It did not lead to the detection of premalignant lesions or endometrial cancer. However, two women presented with symptoms at 6 and 24 months after a normal ultrasound and were diagnosed with endometrial cancer. Both tumours were in an early stage (Figo I). In another study from the Netherlands, 41 women from families with Lynch syndrome underwent surveillance by transvaginal ultrasound (TVU) followed by aspiration biopsy in suspected cases. After a mean follow-up of 5 years, premalignant lesions—that is, complex atypia—were detected in three patients. There was one interval cancer diagnosed 8 months after a normal ultrasound. This tumour was at an early stage. A recent study of 175 subjects from Finland reported the results of surveillance by TVU and aspiration biopsy.<sup>49</sup> Complex atypia was found in 5 patients, endometrial cancer was found in 11, and there were 2 interval cancers. Out of the 11 screen-detected cancers, 6 cancers were identified only by aspiration biopsy and not by TVU. Table 6 summarises the outcomes of the studies. American investigators reported on a retrospective cohort of 315 women, all mutation carriers, 61 of whom had prophylactic surgery and were then followed up for approximately 10 years. No endometrial cancer or ovarian cancer developed in those women who had prophylactic surgery, whereas 33% of women who did not have surgery developed endometrial cancer and 5.5% developed ovarian cancer.<sup>50</sup>

In conclusion, two of the three available studies suggested that surveillance may lead to the detection of premalignant lesions, and one study suggested that it may also lead to the detection of endometrial cancer at an early stage. More prospective studies are needed to establish the most appropriate screening protocol. Because of the higher risk of developing endometrial cancer in carriers of an *MSH6* mutation, hysterectomy may be suggested to these women after menopause. This surgery may also be considered for carriers of mutations in the other MMR genes, and for women who require surgery for a CRC. In view of the risk of ovarian cancer and the failure of early detection of such tumours by TVU and CA-125 estimation, bilateral salpingo-oophorectomy might be considered in mutation carriers after completion of family planning.

Conclusion: the value of surveillance for endometrial cancer is unknown. Surveillance by gynaecological examination, TVU and aspiration biopsy starting from age 30–35 years may lead to the detection of premalignant lesions and early cancers (category of evidence III, grade C). Prophylactic hysterectomy

and salpingo-oophorectomy may be an option for women with Lynch syndrome, since it substantially reduces site-specific cancers (grade C).

### SURVEILLANCE FOR OTHER RELATED CANCERS

Other cancers associated with Lynch syndrome include cancer of the stomach, ureter, renal pelvis, small bowel, bile ducts and tumours of the brain. The lifetime risk of developing one of these cancers is relatively low (<10%), and may be associated with the underlying MMR defect. The risk of developing gastric cancer may be higher in some countries. The International Society of Gastrointestinal Hereditary Tumours recommends surveillance for cancer of the stomach if the cancer clusters in the family (more than one case).<sup>51</sup> However, the European group is of the opinion that surveillance in families with Lynch syndrome for gastric cancer may also be considered in countries with a high incidence of such tumours.

In the decision-making process regarding which surveillance protocol should be recommended, a reasonable approach might be first to discuss all the various cancer risks with the patient, then discuss which screening protocols are established as effective based on published evidence—for example, colon and possibly endometrium screening (see above). Finally, the doctor and patient should weigh up the possible benefits versus costs and risks for screening for other cancers. In addition, it should be recommended to all at-risk family members that they should contact a doctor early if they are worried about specific signs or symptoms.

Table 7 summarises the guidelines for surveillance of families with Lynch syndrome recommended by the collaborative group of the European experts in hereditary gastrointestinal cancer. This protocol is indicated in families with an identified MMR defect, and also in families with clustering of CRC and other related cancers with evidence of MMR deficiency—for example, by the presence of MSI or loss of expression in tumours (with the exception of families of patients with such features caused by hypermethylation of *MLH1*).

### SURGICAL MANAGEMENT OF COLORECTAL CANCER

Several studies have shown that patients with Lynch syndrome have an increased risk of developing multiple (synchronous and metachronous) CRCs. Thus, before resection of a colon tumour, it is important to visualise the complete colon, because of the risk of a synchronous tumour.

Question: what is the best surgical treatment for a patient who is diagnosed with CRC associated with Lynch syndrome?

A Dutch study reported that the risk of developing a second colon tumour after treatment of a primary CRC in Lynch syndrome was 16% after 10 years of follow-up.<sup>41</sup> In view of this substantial risk, the question arises whether a subtotal colectomy instead of a segmental resection might be the preferred treatment in patients from families with Lynch syndrome with a primary tumour. In a recent study, a decision analysis was performed to compare the life expectancy for patients undergoing subtotal colectomy or partial resection for a primary screen-detected CRC.<sup>52</sup> The results indicated that subtotal colectomy performed at a young age ( $\leq 47$  years) would lead to an increased life expectancy of up to 2.3 years. Unfortunately, the authors were not able to use quality of life (QoL)-adjusted life expectancy, because studies on QoL that specifically consider patients with Lynch syndrome were not available in the literature. Although for sporadic CRC QoL after segmental resection has been reported to be better than that after subtotal colectomy, in families with Lynch syndrome, QoL after segmental resection may be decreased by the need for colonoscopy (vs sigmoidoscopy after subtotal colectomy) and the fear of a second tumour.

**Table 6** The outcome of surveillance for endometrial cancer in families with Lynch syndrome

Figo III	—	—	1

—, not found; TVU, transvaginal ultrasound.  
\*Including one occult cancer detected at surgery.

Based on these findings and the substantial risk of developing a second tumour, subtotal colectomy with ileorectal anastomosis can be considered if colon cancer is detected in a young patient participating in a surveillance programme. A prospective study that also addresses QoL should evaluate which surgical option is the most appropriate in Lynch syndrome. Until the outcome of such studies is available, the Mallorca group recommends discussing the pros and cons of both options with a patient from a family with Lynch syndrome who develops CRC.

Conclusion: regarding the treatment of CRC in patients from families with Lynch syndrome, no controlled trials are available; one decision analysis study has reported an increase in life expectancy with subtotal colectomy compared with partial resection; in view of this study and the high risk of a second CRC, the option of extensive resection should be discussed in young patients (eg, <50 years; category of evidence III, grade C).

## CHEMOTHERAPY

Currently, at least three chemotherapeutic agents have been proven to be effective in the treatment of CRC—that is, 5-FU with or without leucovorin, oxaliplatin and irinotecan (CPT11). Unfortunately, the effectiveness of these agents in patients with MSI-H or Lynch syndrome tumours is unknown. In vitro studies have suggested that MMR-deficient colon cancer cells might not respond to 5-FU-based chemotherapy.<sup>53</sup> On the other hand, CRC cell lines defective in MMR exhibit increased sensitivity to CPT11.<sup>54</sup>

Question: is chemotherapy effective in patients with MSI-H tumours?

The effect of chemotherapy in patients with MSI-H or HNPCC tumours has been reported in only a few studies (table 8).<sup>55–59</sup> Most studies showed that there was no benefit of 5-FU treatment in such patients. One small study on stage IV CRC patients reported complete or partial responses to treatment with irinotecan in 4 of 7 patients with MSI-H tumours, compared with 7 of 65 patients with MSI-L/MSS tumours.<sup>59</sup>

Because most studies are retrospective, all authors urge caution in implementing these findings in clinical practice until they are confirmed by prospective studies. Because it may be unethical to withhold chemotherapy in a clinical trial for potentially curable advanced-stage colon cancer, the best format of such studies is to compare effective drugs such as CPT11 or oxaliplatin with 5-FU.

Conclusion: experimental and clinical studies suggest that MSI-H tumours are resistant to 5-FU-based chemotherapy; however, prospective clinical trials are needed before definitive recommendations can be given (category of evidence III).

## DISCUSSION

The guidelines for the management of Lynch syndrome provided in this manuscript are the result of intensive discussions among the participants of a 2-day workshop held in Mallorca in April 2006. Because most of the studies that form the basis for the recommendations were descriptive and/or retrospective in nature, many of these recommendations were

**Table 7** Surveillance protocol in Lynch syndrome and familial clustering of colorectal cancer

Disorder	Lower age limit (years)	Examination	Interval (years)
Lynch syndrome	20–25	Colonoscopy	1–2
	30–35	Gynaecological examination, transvaginal ultrasound, aspiration biopsy	1–2
	30–35	Gastroduodenoscopy*	1–2
	30–35	Abdominal ultrasound, urinalysis and cytology urine†	1–2
Familial clustering of colorectal cancer without evidence of MSI‡	45–50 or 5–10 before age at diagnosis of first CRC in family	Colonoscopy	3–5

CRC, colorectal cancer; MSI, microsatellite instability.

\*If gastric cancer runs in the family or in countries with a high incidence of gastric cancer.

†If urinary tract cancer runs in the family.

‡Amsterdam positive families.

**Table 8** Studies on the effectiveness of chemotherapy in patients with MSI-H tumours

Author, year	Type of study and selection criteria	Agents	Patients with MSI-H tumour	Effect of chemotherapy
Liang <i>et al.</i> , <sup>55</sup> 2002	Prospective, non-randomised; stage IV CRC	High-dose 5-FU/leucovorin	52	Better survival in patients with MSI-H tumours who received chemotherapy
Ribic <i>et al.</i> , <sup>56</sup> 2003	Retrospective MSI analysis of tumours from patients who participated in a multicentre RCT 20–25 years ago; CRC stage II/III	5-FU/leucovorin or levamisol	95	No survival differences
Carethers <i>et al.</i> , <sup>57</sup> 2004	Retrospective, consecutive patients; CRC stage II/III	5-FU-based	36	No survival differences
De Vos <i>et al.</i> , <sup>58</sup> 2004	Retrospective, CRC stage III patients from families with HNPCC	5-FU/leucovorin or levamisol	92	No survival differences
Fallik <i>et al.</i> , <sup>59</sup> 2003	Non-randomised controlled trial; CRC stage IV	Irinotecan (CPT11)	7	3 partial and 1 complete response

CRC, colorectal cancer; FU, fluorouracil; HNPCC, hereditary non-polyposis colorectal cancer; MSI, microsatellite instability; RCT, randomised controlled trial.

based on expert opinion, and we were fortunate to convene an extensive expert panel. During the workshop, it became clear that there are still many aspects of Lynch syndrome about which new knowledge needs to be gained through further research.

Regarding the identification of Lynch syndrome, the available criteria (revised Bethesda guidelines) seemed to be effective for the selection of families for analysis of tumour MMR status. However, even with the use of these guidelines, a significant proportion of mutation carriers may be missed. The sensitivity of the Bethesda criteria might be improved by investigating these missed cases. For example, since most missed mutation carriers are diagnosed with CRC between age 50 and 60 years, it may be appropriate to increase the age at diagnosis below which MSI analysis is recommended. Another possibility might be to evaluate all CRCs, for example by IHC. Because there is increasing evidence that MSI/IHC is an important prognostic factor and may predict the response to chemotherapy, these tests might in future be performed on a much larger scale, if not in all CRC cases.

Studies have shown that colorectal surveillance in Lynch syndrome leads to a reduction of CRC and associated mortality. However, a substantial proportion (estimated at 5–10% per 10 years of follow-up) of patients develop (interval) cancers under surveillance. For this reason, future research should address how new screening tools such as chromoendoscopy, high-resolution colonoscopy with narrow banding or DNA analysis of the faeces might help in the early detection of colorectal tumours.<sup>60</sup>

Very few data are available on the effectiveness of surveillance for endometrial cancer. A prospective trial in which TVU is being compared with TVU and aspiration biopsy should be undertaken.

For patients with Lynch syndrome who present with CRC, the surgical choice lies between partial resection and more extensive surgery such as subtotal colectomy and ileorectal anastomosis. In view of the increased risk of developing a second tumour and also the evidence for improved life expectancy after extensive surgery, the best option seems to be a subtotal colectomy. However, because such an extensive surgical procedure might have significant impact on the QoL, a randomised controlled trial should be performed, which includes assessment of the QoL and functional outcome after the two procedures.

The use of chemotherapy in patients with Lynch syndrome having CRC, or in patients with MSI-H tumours, is controversial. Because of the effective surveillance programmes, few patients with metastatic disease are currently being identified. Therefore, future trials on the effect of various chemotherapeutic regimens in Lynch syndrome or in patients with MSI-high tumours should be conducted on a European level or even worldwide.

There is ample evidence that the expression of Lynch syndrome is influenced by environmental factors. However, studies that indicate which environmental factors play a significant role are rare. Since 1998, the effect of resistant starch and aspirin has been investigated in a large randomised placebo-controlled trial with families having Lynch syndrome from all over the world (<http://www.CAPPs.com>). The results will be published in 2007. A new trial (the Prevention of Endometrial Tumours trial) is being developed to explore the possibility of chemoprevention using the progesterone-releasing Mirena intrauterine device.

In conclusion, the guidelines described in this manuscript may be helpful for the appropriate management of families with Lynch syndrome. There is an urgent need for prospective controlled studies to improve the care of these families further.

The workshop in Mallorca identified several collaborative studies the group will focus on to clarify some of the controversial issues that exist in the clinical management of Lynch syndrome.

High-frequency microsatellite instability predicts better chemosensitivity to high-dose 5-fluorouracil plus leucovorin chemotherapy for stage IV sporadic colorectal cancer after palliative bowel resection. *Int J Cancer* 2002;**101**:519–25.
- 56 **Ribic CM**, Sargent DJ, Moore MJ, Thibodeau SN, French AJ, Goldberg RM, Hamilton SR, Laurent-Puig P, Gryfe R, Shepherd LE, Tu D, Redston M, Gallinger S. Tumor microsatellite-instability status as a predictor of benefit from fluorouracil-based adjuvant chemotherapy for colon cancer. *N Engl J Med* 2003;**349**:247–57.
- 57 **Carethers JM**, Smith EJ, Behling CA, Nguyen L, Tajima A, Doctolero RT, Cabrera BL, Goel A, Arnold CA, Miyai K, Boland CR. Use of 5-fluorouracil and survival in patients with microsatellite-unstable colorectal cancer. *Gastroenterology* 2004;**126**:394–401.
- 58 **de Vos tot Nederveen Cappel WH**, Meulenbeld HJ, Kleibeuker JH, Nagengast FM, Menko FH, Griffioen G, Cats A, Morreau H, Gelderblom H, Vasen HF. Survival after adjuvant 5-FU treatment for stage III colon cancer in hereditary nonpolyposis colorectal cancer. *Int J Cancer* 2004;**109**:468–71.
- 59 **Fallik D**, Borriani F, Boige V, Viguier J, Jacob S, Miquel C, Sabourin JC, Ducreux M, Praz F. Microsatellite instability is a predictive factor of the tumor response to irinotecan in patients with advanced colorectal cancer. *Cancer Res* 2003;**63**:5738–44.
- 60 **Hurlstone DP**, Karajeh M, Cross SS, McAlindon ME, Brown S, Hunter MD, Sanders DS. The role of high-magnification-chromoscopic colonoscopy in hereditary nonpolyposis colorectal cancer screening: a prospective “back-to-back” endoscopic study. *Am J Gastroenterol* 2005;**100**:2167–73.

### See your work published in *Journal of Medical Genetics*

*Journal of Medical Genetics* is only as good as its articles, so we work hard to support the authors who trust us to publish their work. Here are just a few reasons why you should send us your article:

- **Academic credibility** – You’ll be published in one of the top medical genetics journals in Europe.
- **Maximum visibility for your article** – Your work will be seen by a wide international audience, both through the print journal (C 1500 readers per issue) and the website (~42,000 unique visitors every month).
- **Hassle free peer review** – Our fast and efficient submission process involves only the best reviewers. The entire submission and peer review process is conducted online, saving you time and shortening the wait for your paper to be published.
- **Online First** – Your article may appear on the journal website as soon as it’s accepted via our ‘Online First’ feature. Your colleagues could be reading your paper within days of you submitting it.

For more information or to submit an article visit [www.jmg.bmj.com](http://www.jmg.bmj.com) and click the **Online Submissions** button.
